We study self-propulsion of a half-metal coated colloidal particle under laser irradiation. The motion is caused by self-thermophoresis: i.e. absorption of laser at the metal-coated side of the particle creates local temperature gradient which in turn drives the particle by thermophoresis. To clarify the mechanism, temperature distribution and a thermal slip flow field around a micro-scale Janus particle are measured for the first time. With measured temperature drop across the particle, the speed of self-propulsion is corroborated with the prediction based on accessible parameters. As an application for driving micro-machine, a micro-rotor heat engine is demonstrated.

Self-propulsion arouses interests among scientists because of its interesting dynamics, associated theoretical challenges to nonequilibrium transport phenomena, and possible applications, including micro-swimmer, nano-machine and drug delivery [1–4]. Biological self-propelled molecules or biomotors [5–7], such as ATPase and myosin, convert chemical energy to mechanical motion through chemo-mechanical coupling. Such thermodynamic coupling also causes self-propulsion in physical systems as exemplified by nano-rods motion in hydrogen peroxide solutions [8]. In contrast to self-propulsion, phoretic motions, such as electrophoresis, dielectrophoresis and thermophoresis, generally described by the linear response theory, are the directional motions of material in given external fields. To make a bridge between a phoresis and a self-phoretic motion [9] would give more insights into the mechanisms for self-propulsion. In this paper, we produced Janus particles (the particle containing two different surfaces on its two sides [10]), by evaporating gold coat on the hemisphere of silica or polystyrene spheres, and analyzed self-propulsive motion under the laser irradiation. The Janus particle moves along a local temperature gradient which is generated by absorption of laser at the metal-coated hemisphere. The local driving gradient and flow near a micro-scale Janus particle are experimentally observed for the first time.

Thermophoresis of colloids in solution is intensively discussed recently [11, 12] motivated by new experimental observations. To utilize thermophoresis as a mechanism for self-propulsion of a particle, it is essential to create a local temperature gradient by the particle itself. To prepare Janus particles, a mono-layer of micro-scale silica or polystyrene spheres is prepared by a drying process. Gold is deposited by thermal evaporation to create 25 nm thick coating on the half side of each particle [13]. The coating of gold can be visualized under an optical microscope. An image of 1 µm Au-silica Janus particles is shown in Fig. 1(a) and (b). The dark side of the particle has an Au coating, which does not transmit light and thus darker than the other side (silica).

A schematic figure of experimental configuration is shown in Fig. 1(c). A thin chamber containing a solution and particles is sandwiched by two cover glasses with a 20 µm spacer. The cover glasses are treated by BSA to prevent particles from sticking to the surfaces. A laser (Nd:YAG, 1064 nm) is fed from the bottom of the chamber through an oil immersion objective (100X NA 1.35. The laser is defocused to irradiate a wider area of a diameter about 9 µm. Images of particles are collected through the same objective by a high speed camera at 300 frames per second.

In the experiment, 1 µm Au-silica Janus particles are placed in a chamber at a low concentration to insure only one particle caught within the view under the microscope. After applying the laser, a particle is pushed to the upper surface of the chamber and moves around within the laser irradiated region. The two-dimensional trajectories of a particle in different conditions are shown in Fig. 1(d)-(f).
We observed that the particle moves faster under laser irradiation than the normal diffusion and the direction of motion follows the polarity of the Janus particle (See movie-1 in Supplementary Information). We measured the mean square displacement (MSD) of the moving particle. The MSD for different laser irradiation powers are shown in Fig. 2(a). The power of the laser is varied from 0 to 40 mW before the objective. We observed that the irradiation of the laser increases the MSD several folds for a short time scale (\( \leq 1 \) second) and the confinement of the particle for a longer time scale (\( \geq 3 \) seconds). The latter can be explained by the two-dimensional trapping effect due to strong scattering from the metal part of particle [14], although the laser is defocused. On the other hand, the behavior at the shorter time scale cannot be attributed by the trapping effect.

Based on these observations, we consider that the dynamics of a Janus particle is composed of three kinds of motions, Brownian motion, self-propelled motion induced by the laser, and optical trapping confinement. These three kinds of motions can be separated by two different time scales: the time constant \( \sigma_k \) of the laser trapping effect and the rotational diffusion time constant \( \tau_r \) of self-propelled motion induced by the laser.

To discuss the time scale of the trapping effect, we employ the motion of a self-propelled particle in a harmonic potential without inertia as a first approximation. The MSD of the particle can be obtained as (See SI),

\[
MSD = 4D\tau_k(1 - e^{-t/\tau_k}) - \frac{2V^2}{\tau_k + \tau_r}e^{-t/\tau_r} + \frac{2V^2}{\tau_k + \tau_r}(1 + \frac{2}{\tau_r}e^{-t/\tau_r}),
\]

(1)

where \( \tilde{\tau} = 1/(\tau^{-1} + \tau_k^{-1}) \), \( D_r = 1/2\tau_r \) is the rotational diffusion constant, \( D \) is the diffusion constant of the particle, \( V \) the self-propelling velocity, \( k \) the spring constant, \( \tau_k = k_BT/Dk \) the time constant due to the harmonic potential, \( T \) the temperature, and \( k_B \) is Boltzmann constant. When \( \tau_k \gg \tau_r \), Eq. (1) tends to \( MSD \approx (4D + 2V^2\tau_r\tau_k)(1 - e^{-t/\tau_r}) \),

thus \( \tau_k \) can be obtained from MSD and Eq. (1) by an approximation. The values of \( \tau_k \) are from 0.4 to 3 s depending on the laser power.

The self-propelled motion along the particle’s polarity \( n(t) \) is characterized by the rotational diffusion of the polarity. By measuring polarity of the particle from the images, the rotational diffusion time constant \( \tau_r \) was obtained by calculating the correlation function \( \langle n(t) \cdot n(0) \rangle = \exp(-t/\tau_r) \) (data not shown). The values of \( \tau_r \) are typically fitted between 0.1 to 0.2 s depending on the laser power. In a short time scale, \( t \ll \tau_r \ll \tau_k \), the rotational diffusion and the trapping effect can be neglected, the motion can be treated as Brownian motion with a fixed directed motion. The MSD of Eq. (1) in a short time scale becomes,

\[
MSD = 4Dt + V^2t^2.
\]

(2)

The contribution from Brownian motion is \( 4Dt \) and that of directed motion is \( V^2t^2 \). Similar behavior in hydrogen peroxide solutions but without potential has been discussed [15]. The MSD in the short time scale are shown in Fig. 2(b). Eq. (2) is used to fit the MSD up to 0.1 s to obtain a set of different \( V \) values for different laser powers with a fixed \( D \). The data can be well fitted by Eq. (2) and \( D \) is obtained as 0.38 \( \mu m^2/s \). Comparing with diffusion of a free particle (0.47 \( \mu m^2/s \)), smaller value might be caused by the additional friction over the wall. The relation between self-propelling velocity \( V \) and the laser irradiation power is shown in the inset of Fig. 2(b). The overall linear relation confirms that the self-propulsion of a particle is powered by the laser irradiation linearly.

We propose that the directed motion of Janus particle is induced by the temperature gradient generated by itself which we call self-thermophoresis. The metal side absorbs the laser of the intensity \( I \) with an absorption efficiency \( \epsilon \). The heat generation at the surface of the particles with the radius \( R \) is balanced with thermal diffusion thus gives \( q(\theta) = \kappa e_n \cdot \nabla T \) where \( \kappa \) is the heat conductivity of water and \( e_n \) is the outward normal unit vector on the surface.

The temperature distribution on the surface can be obtained by solving heat transfer equation as

\[
T(R) = T_0 + \sum_{n=1}^{\infty} \frac{q_n R}{(n+1)\kappa_0 + n\kappa_i} P_n(\cos \theta)
\]

(3)

where \( T_0 \) is the temperature at infinity and \( P_n(\cos \theta) \) is the Legendre polynomial of order \( n \). The thermal conductivity inside and outside the particle is \( \kappa_i \) and \( \kappa_o \), respectively. The heat flux \( q(\theta) \) is expanded using the polynomial with the coefficients \( q_n \). The temperature is asymmetric around the particle due to half-side absorption. The gap of temperature across the two sides of Janus particles is \( \Delta T = 3\epsilon I R/(2(\kappa_o + \kappa_i)) \).

The propulsive velocity \( V \) for a self-thermophoretic particle is given by a surface integral of effective surface slip velocity \( v_s = \mu(\theta) \nabla T \) driven by local temperature gradient \( \nabla T \). \( \mu(\theta) \) is mobility characterized by interactions between the particle and fluids. On the other hand, exactly the same gradient is imposed externally in which the velocity is described by the Soret coefficient, \( S_T = D_T/D \) as \( u = DS_T \nabla T \). Here \( D_T \) is the thermodiffusion coefficient. This suggests that the self-thermophoretic velocity is described not only by...
The mobility but also by the Soret coefficient, which has been rather extensively studied (see SI). The velocity is

\[ V = -DS_T \frac{\Delta T}{3R}, \]

where \( S_T \) of Janus particle is interpreted as the average of the two coefficients of silica beads and those covered uniformly by gold. In Eq. (4), \( \Delta T \) is proportional to the laser power and accordingly velocity \( V \) is proportional to it, which agrees with the MSD measurements. To further verify the proposed self-phoretic mechanism, the flow and temperature around a Janus particle and the magnitude and sign of Soret coefficient are compared with observations in the following.

The flow around a spherical colloid in temperature gradient was reported recently [10]. We expect a similar flow caused by self-thermophoresis might exist around Janus particle. The flow around a laser irradiated Janus particle is observed by fixing a 3 \( \mu m \) Au-polystyrene Janus particle on the surface. 40 nm polystyrene fluorescent particles are added to the solution as tracers. The distribution of tracers and motion of a large tracer are shown in Fig. 3(a). The motion of a large tracer clearly shows the direction of the circulating flow near the heated Janus particle. We also found that the concentration of tracers is high in the non-coating side and low in the coating side. It can be explained by the balance between the drag by the thermal slip flow induced by Janus particle and the thermophoresis of the tracer itself. Tracers near the particle surface are driven from colder to hotter region by the thermal slip and reinjected to the colder side by the circulation. But the tracers are repelled from the hotter region due to positive Soret effect, resulting in higher density of tracers at the colder side of the Janus particle.

The temperature profile was directly measured for an Au-polystyrene Janus particle with the diameter of 3 \( \mu m \) fixed on the cover glass and subjected to laser heating. To do this, we used a temperature sensitive fluorescent dye, bis(2-carboxylethyl)5,6-carboxyfluorescein (BCECF) [17]. The temperature profile is shown in Fig. 3(b), where the laser power is 100 mW and the diameter of the irradiated region is 25 \( \mu m \). Here larger irradiated region is adopted to scale up the length scale together with the particle size (from 1 \( \mu m \) to 3 \( \mu m \)). The average laser intensity per unit area \( I \) is equal to the condition where the laser power is 13 mW in the 9 \( \mu m \)-diameter region. The result shows that the temperature in the coated side is about 2 K higher than the non-coated side (Fig. 3(b)). The temperature profile also agrees with the analytic result shown in Eq. (3). For a 1 \( \mu m \) bead, the temperature profile is hard to obtain experimentally; the temperature gap \( \Delta T \) across the particle is estimated as about 0.7 K based on 3 \( \mu m \) data. By using the velocity data in Fig. 2(b) inset, we can estimate \( S_T \) from Eq. (4) as 10 K\(^{-1}\). This result is consistent with independently measured the Soret coefficient (26 K\(^{-1}\)) of Au-silica Janus particle.

Recently, it has been shown that the thermophoretic property of particles can be changed by adding surfactant, which would be absorbed on the surface of particles [18]. The sign of Soret coefficient of Janus particle is determined by single particle tracing experiments in an externally applied temperature gradient using an optically heated chamber, where the laser is focused on the top glass plate of the chamber whose surface is coated by Chromium [19, 20]. It shows that the Soret coefficient of Janus particles is positive in water (moving to a colder region). Next, we add Triton X-100 to the solution (0.05 wt.%). We find that the Soret coefficient of Janus particles become negative in Triton X-100 solution (particles move to warmer region). Fig. 3(c) is the schematic figure of the directions of thermophoretic motion of a Janus particle in a temperature gradient.

We measured the angle \( \Delta \theta \) between the direction of the motion and the polarity of Janus particles in water and Triton X-100 solution as shown in Fig. 3(d). The distribution of \( \Delta \theta \) of a Janus particle for two conditions are shown in Fig. 3(d)(e). It shows that the motion of a Janus particle is directed from metal side to silica side in pure water, implying toward colder side in the lo-
We report the self-propulsion of Janus particles under a wide laser irradiation. The mechanism of active motion is explained by the self-thermophoresis. The direction of motion is determined by the polarity of a Janus particle in contrast to the phoretic motions guided by the external fields. The external field induced self-propulsion gives us a new way to power and control micro-machines. The basic principle is similar to the Crookes radiometer \[21\], but the scale is much more reduced.
